ABSTRACT

This report presents a specific method of programming a digital computer to construct and evaluate codes suitable for use in a burst-error correction decoding scheme described in the Tenth Scientific Report. Two (100,50) codes of this type have been constructed using the methods described. One is found capable of correcting uniquely all bursts of length 21 or less.

The method used to evaluate burst-error correcting capabilities is applicable to any group code, not just the class under consideration. Memory limitations have restricted the present program to code lengths not exceeding 105 digits, of which at most 63 may be check digits.

GLOSSARY

В	-	set of error burst sequences
b	-	maximum correctible burst length
c	_	number of check digits per code word
° ₁	-	i th check digit
[e _i]	-	partial error sequence
$[e_{1}]_{A}$	-	error sequence
ij	-	j th information digit
k	-	number of information digits per code word
[M]	-	matrix relating information digits to check digits
$[M_1], [M_2]$	-	submatrices of [M]
n	-	number of digits in a code word
P	_	record of column under consideration
P _s	-	record of columns already considered, including present
$\mathtt{p_i}$	-	i th parity digit
[P]	-	parity check, or coding, matrix
$[P_1], [P_2], \dots, [P_q]$	-	submatrices of [P], all of which have inverses
[p]	-	parity sequence
Q	-	number of decoding matrices
$[9_1], [9_2], [9_3], \dots$	-	decoding matrices
R	-	random number
r _i	-	i th received digit
[R ₁],[R ₂]	-	submatrices used in second construction method

[r]	- received sequence
s _i	- i th set of columns
x	- first part of set of columns
x	- amount of overlap of two matrices
Y	- second part of set of columns
Y	- initial second part of set of columns

A. Introduction and Basic Theory

The Tenth Scientific Report¹ described a coding and decoding method for burst-error correction. The coding and decoding processes are fairly simple, but the actual construction and evaluation of a code is difficult. The purpose of this report is to give a specific method for constructing such a code and evaluating its correction capabilities, and to illustrate codes actually constructed by this method.

The theory of the burst-error correction procedure for randomly chosen group codes was given in the Tenth Scientific Report. Only the basic ideas needed for an understanding of the results will be repeated here.

In an (n,k) group code,² the n-k = c check digits c_i may be computed from the k information digits i_j by the matrix equation

$$\begin{bmatrix} c_1 \\ c_2 \\ \vdots \\ \vdots \\ \vdots \\ c_c \end{bmatrix} = [M] \cdot \begin{bmatrix} i_1 \\ i_2 \\ \vdots \\ \vdots \\ i_k \end{bmatrix}, \qquad (1)$$

where [M] is a c x k matrix of ones and zeroes, and addition is modulo two.

Let the last c digits in a transmitted code word be the check digits. When a sequence of binary digits r_1 (i=1, 2, ..., n) representing message plus noise is received, a parity sequence can be formed:

where [I] is a c x c unit diagonal matrix. In abbreviated form, (2) may be written as

$$[p] = [P][r] . (3)$$

The received sequence can be considered as the modulo two digit-by-digit sum of the transmitted sequence and a noise (or error) sequence. The group of 2ⁿ possible error sequences can be partitioned into 2^c cosets of the group of code words. All the sequences in each coset have the same parity sequence and no two sequences in different cosets have the same parity sequence.²

The error correction procedure is based on a set of hypotheses that the errors are all within given blocks of c positions of the received sequence. A set of c x c matrices $[P_1]$, $[P_2]$, ..., $[P_q]$ is chosen, such that $[P_1]$ consists of the columns 1 to c of [P], $[P_2]$ consists of the columns c - x + 1 to 2c - x (x \geq b), etc., so that q

is the smallest integer for which each matrix overlaps the preceding one in at least b positions, and every position is included in at least one matrix. The value of q is the smallest integer equal to or greater than (n-b)/(c-b).

Let B be the set of error sequences consisting of bursts of length b or less. Assume that:

- 1) no two elements of B appear in the same coset and
- 2) each matrix [P,] has an inverse.

The decoding procedure can then correct uniquely every element of B.

The quantities

$$[e_1] = [P_1]^{-1} [P] [r] = [Q_1] [r]$$
 (4)

are calculated. The error sequence corresponding to $[e_1]$ is $[e_1]_A$, where $[e_1]_A$ is obtained from $[e_1]$ by augmenting $[e_1]$ with c zeroes corresponding to the positions hypothesized to be error-free. If one of the $[e_1]_A$ ϵ B, the procedure is to add that $[e_1]_A$ to [r]. If no $[e_1]_A$ ϵ B, the code word is rejected and a repeat is requested.

B. Specific Codes

Two (100,50) codes were constructed in a random manner with the aid of a Packard Bell pb 250 computer. The better of the two codes is illustrated in this section. The other is shown in Appendix H. Additional codes could be constructed and evaluated at a rate of about one every 4-5 hours.

Methods of construction are described in Section C, and further details of the construction program are given in Appendices B and C.

The method of evaluation is given in Section D and Appendix D.

B-L. Coding and Decoding Matrices for a Particular Code

The coding matrix [P] for a particular (100,50) code is shown in figure 1. The digits of the matrix are represented octally, each octal digit representing three successive binary digits in a row of the matrix. Since 100 is not a multiple of 3, the last octal digit in a row represents only a single binary digit, being a 4 or a 0, according as the binary digit is a 1 or a 0, respectively. The + signs should be ignored.

Three decoding matrices are required, covering the sets of positions 1-50, 26-75, and 51-100, respectively. These matrices are of the form:

$$[Q_1] = [P_1]^{-1} [P]$$
; (5)

$$[Q_2] = [P_2]^{-1} [P]$$
 ; (6)

and
$$[Q_x] = [P_x]^{-1} [P] = [P]$$
 (7)

Figure 1 - Coding (and Decoding) Matrix [P] for a (100, 50) Code [key = +3574263]

Since $[P_3]^{-1} = [I]$, the third decoding matrix is just [P] itself. The other two are shown in figures 2 and 3.

(Actually, any one of the three matrices in figures 1, 2, and 3, can be chosen as the coding matrix. The only difference would be in the check digit locations. If figure 2 were the coding matrix, the check digits would occupy positions 26-75, while if figure 3 were the coding matrix they would occupy positions 1-50).

Although the above code appears to be random, and can be considered to be random for its intended use, it was actually generated by the computer in a deterministic manner by successive multiplications and retention of the minor product. The entire code can always be regenerated by means of the key number + 3574263. How this is done will be explained in Appendix B. The code described in Appendix H was not generated in this manner, but was constructed from random numbers taken partly from a table of random numbers, and partly from digits selected from the decimal expansion of the natural logarithmic base e. It is recommended, however, that any future codes be constructed by the much simpler process of computer generation.

B-2. Error-Correcting Capabilities

It was found that the code whose matrix is shown in figure 1 is capable of correcting uniquely all error bursts of length 21 or less, but not including all bursts of length 22. The other chosen code was found capable of correcting all error bursts of length 18 or less, but not all bursts of length 19.

Figure 3 - Decoding Matrix $Q_{\mathbf{0}}$ for the (100, 50) Code

It was shown in Section V.B of reference 1 that of the (100,50) codes for which all $[P_1]$ have inverses, at least 79 percent can correct all bursts of length 19 or less, and at least 18 percent can correct all bursts of length 20 or less. The bound does not guarantee that any (100,50) code could correct all bursts of length 21 or less. The fact that one of two selected codes could correct all bursts of length 21 or less suggests that the bound is somewhat pessimistic. A definite upper bound on the maximum burst length is c/2, or 25 in this case.

The method by which the error-correcting capability of the codes were determined is described in Section D and Appendix D.

B-3. Implementation of the Decoding Procedure

Although the selection and evaluation of a code is difficult, its actual implementation is not difficult. The matrix decoding operations can be carried out by means of a very elementary type of magnetic core matrix, as shown in figure 4.

A core is placed at an intersection if and only if the intersection of row i with column j of the matrix is a one. (Dummy cores can be placed at other intersections, if necessary). The cores are originally set in their zero state. When the first digit is received, the first vertical wire is energized if and only if the digit is a one, and a pulse passes along all horizontal wires which intersect with the first vertical wire at a core. Later received digits act in a similar manner. Flip-flops on each horizontal wire record zero or one according as an even or odd number of impulses have occurred on that wire.

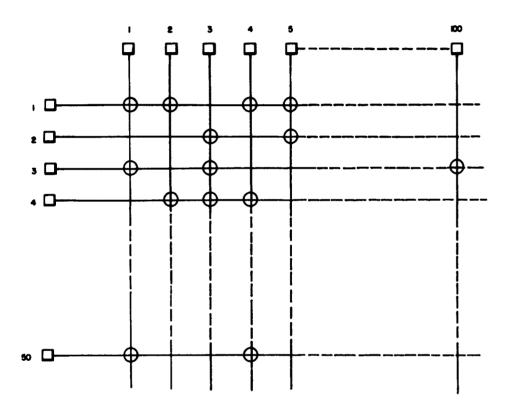

FIG. 4
A MAGNETIC CORE DECODING MATRIX

A total of three such matrices are required for the (100,50) code. The contents of the 50 flip-flops in the ith matrix represent [e_i], and if one of the three [e_i] corresponds to a burst of length b or less, that [e_i] is added to the appropriate 50 digits of the 100-digit received sequence. Otherwise, the sequence is rejected and a repeat requested.

The matrix requires only two wires through each core instead of the usual three and in this respect is easier to construct than standard core matrices. On the other hand, the fact that genuine cores are placed only at fairly random intersections may make the matrix somewhat more difficult to construct.

C. Construction of the Code

If [P] is the coding matrix of a (100,50) group code, it is required for the burst-error correcting procedure that the following sets of columns of [P] be linearly independent:

columns 1 to 50; columns 26 to 75; columns 51 to 100.

One of these sets may be chosen to correspond to the parity check digit positions and is thus a unit diagonal matrix. The remaining 50 columns, which are designated as [M], may be chosen in a random manner, subject to the restriction that the appropriate sets of columns of [P] be linearly independent.

One method of finding a suitable matrix [M] is to select matrices at random until one is found which satisfies the linear independence conditions. Approximately one matrix in twelve is suitable for codes of rate 1/2 (see p. 31 of ref. 1).

A second method of finding a suitable code is to begin with a diagonal matrix and then form random combinations of rows. This method has the advantage that the linear independence requirement is automatically satisfied without an indefinite number of successive trials, but the disadvantage that the coding matrix is not constructed in one whole unit, but must be built up from the random matrices with inverses which have been constructed.

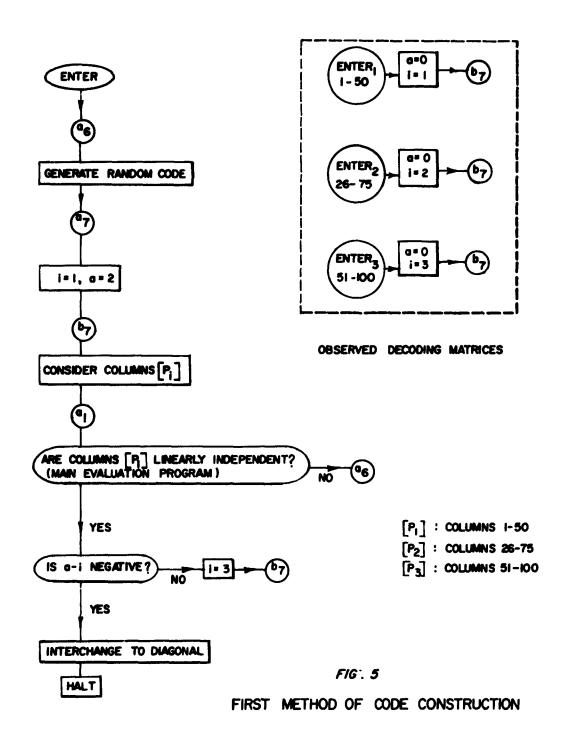

The first method is preferable given the present programs, because it is more compatible with the evaluation program and requires fewer manual operations.

C-L. First Method

Figure 5 shows the general block diagram for this procedure. The connectors a, etc., refer to more detailed diagrams given in Appendices B and D.

First, a random (100,50) code is generated by constructing the matrix [P] of random numbers except for a unit diagonalised 50 x 50 matrix in columns 26-75. Then, the linear independence of columns 1-50 is investigated (i=1) with the aid of the code evaluation program. (This program is described in Section D and Appendix D). If they are linearly dependent, a new code is generated. If they are linearly independent, columns 51-100 are tested for linear independence, (i=3). If these are also linearly independent, a suitable code has been found.

Immediately after a code has been found suitable, the form of the coding matrix is such that a single one appears in each of columns 51-100. Rows are then interchanged so that columns 51-100 form a unit diagonal matrix, thereby yielding the matrix [P]. By setting i=1 and a=0, as shown in figure 5, columns 1-50 can be diagonalized, forming the decoding matrix $[Q_1]$. The other decoding matrix, $[Q_2]$, is obtained by setting i=2 and a=0. It is always possible to return to the coding matrix [P] (which is also decoding matrix $[Q_3]$) by setting i=3 and a=0.

The first method was used to construct the code described in Section B. Details of a program utilizing the method are given in Appendix B.

C-2. Second Method

The procedure used here for finding a suitable code is to begin with a diagonal matrix and then form random combinations of rows as follows. Replace the first row by the sum of the original first row with a random selection of the other rows. Then replace the second row by the sum of the second row with a random selection of the other rows, using the new first row if this row should be included in the sum. Continue until all rows have been changed. The resulting matrix has an inverse.

In order to use the above procedure, the unit diagonal matrix was chosen to occupy positions 26-75, and the matrix [M] was partitioned into 25 x 25 submatrices as follows:

$$[M] = \begin{bmatrix} R_1 & M_1 & & M_2 \\ ---- & ---- & & \\ M_1 & & R_2 & M_2 \end{bmatrix} , \qquad (8)$$

where the matrices $[M_1]$ and $[M_2]$ are chosen in a random manner, but subject to the restriction that they have inverses. The matrices $[R_1]$ and $[R_2]$ can be selected entirely at random.

The matrices $[P_1]$, $[P_2]$, and $[P_3]$ are then

$$[P_1] = \begin{bmatrix} R_1 & M_1 & & I_{25} \\ ---- & --- & & & \\ M_1 & & & & 0 \end{bmatrix}$$
(9)

$$[P_2] = \begin{bmatrix} I_{25} & 0 \\ ---- & I_{25} \\ 0 & I_{25} \end{bmatrix}$$
(10)

$$[P_3] = \begin{bmatrix} 0 & M_2 \\ ---- & R_2 \\ R_2 & R_2 \end{bmatrix} . \tag{11}$$

The submatrix \mathbf{I}_{25} is a 25 x 25 unit diagonal matrix. The inverses of these matrices are

$$[P_1]^{-1} = \begin{bmatrix} 0 & M_1^{-1} \\ ---- & R_1 \end{bmatrix}$$
(12)

$$[P_2]^{-1} = [P_2]$$
 ; (13)

$$[P_3]^{-1} = \begin{bmatrix} R_2 & I_{25} \\ ----- & 0 \end{bmatrix}$$

$$[P_3]^{-1} = \begin{bmatrix} R_2 & I_{25} \\ ---- & 0 \end{bmatrix}$$
(14)

The three decoding matrices are then

$$[Q_{2}] = [P_{2}]^{-1} [P] = \begin{bmatrix} R_{1} M_{1} & I_{25} & 0 & M_{2} \\ ---- & ---- & ---- & ---- \\ M_{1} & 0 & I_{25} & R_{2} M_{2} \end{bmatrix}; (16)$$

$$[\mathbf{Q}_{5}] = [\mathbf{P}_{5}]^{-1} [\mathbf{P}] = \begin{bmatrix} [\mathbf{R}_{2}\mathbf{R}_{1} + \mathbf{I}]\mathbf{M}_{1} & \mathbf{R}_{2} & \mathbf{I}_{25} & \mathbf{0} \\ ----- & ---- & ---- & ---- \\ \mathbf{M}_{2}^{-1} \mathbf{R}_{1} \mathbf{M}_{1} & \mathbf{M}_{2}^{-1} & \mathbf{0} & \mathbf{I}_{25} \end{bmatrix} .$$
 (17)

One method of finding $[Q_1]$, $[Q_2]$, and $[Q_3]$ is to construct $[M_1]$, $[M_2]$, $[M_1]^{-1}$, $[M_2]^{-1}$, and the other various matrix products and sums involved in (12), (13), and (14). This can be done, and a program for performing all these operations is included in Appendix C. However, once $[Q_2]$ is known, it was found to be more practical to use the code evaluation program to find $[Q_1]$ and $[Q_3]$, as illustrated in figure 5.

The second method was used to construct the code shown in Appendix H. Further details about the program for carrying out this second method are given in Appendix C.

D. Evaluation of the Error-Correcting Capabilities of the Code

D-1. Object and General Approach

It is desired to find the largest value of b for which the code corrects uniquely all bursts of length b or less. For this purpose it is necessary and sufficient to show that each burst of length b or less is contained in a different coset of the group of code words: i.e., that each burst of length b or less is associated with a different parity check sequence.

There are two possible approaches. One is to generate each error burst and observe the decoder outputs. The other is to investigate the structure of the decoding matrix.

The first approach would be practical if a fast special-purpose decoder for the code were already available, but would require a prohibitive length of time for most general-purpose computers. For example, if b = 19, there are about 22 million bursts of length b or less. Since it would be optimistic to assume that the pb 250 could check more than one per second, the procedure would take at least 6000 hours of computing time. Moreover, each additional unit increase of b would approximately double the required time. The second approach is the one used here.

A procedure is found which requires about 3 hours of computing time for b = 21.

D-2. Underlying Principle of the Evaluation Procedure

If the columns of a submatrix [S] consisting of certain columns of [P] are linearly independent, then no two bursts which together

cover positions included entirely in [8] can have the same parity sequence. To prove that a code is capable of correcting uniquely all bursts of length b or less, it is sufficient to show that the following sets of columns, each containing 2b elements, are all linearly independent:

These sets are sufficient because any two bursts must be both included by at least one of the sets.

D-3. The Method

The linear independence of the sets $[S_i]$ is investigated in the order presented above by adding rows of the [P] matrix to other

rows of the [P] matrix. Such operations do not change the linear independence or dependence of any set of columns of the matrix.⁵ The method used is described below with reference to the five parts of figure 6.

A Gauss-Jordan reduction type of operation is employed to determine linear independence. Thus, the first column of the set is searched for a non-zero element (search for pivot - part 3). When one is found, the (pivot) row of [P] containing that element is added modulo two digit-by-digit to all rows whose first column has a non-zero element (perform pivot operation - part 4). Then, a search (search for pivot) is made for a non-zero element in the second column of the set (select new column - part 1), excluding from consideration the previous pivot row. This process is continued until either:

- (a) all members of the set of columns are searched and a non-zero pivot is found for every column, in which case the set is linearly independent; or,
- (b) a column is found with no acceptable pivot, in which case the set is linearly dependent.

If $[S_1]$ is found to be linearly independent, $[S_2]$ is next investigated. (Change set of columns - part 2). Since $[S_1]$ and $[S_2]$ are identical except in one column, it is only necessary to investigate one column of $[S_2]$ to determine its linear independence once $[S_1]$ has been found linearly independent. (Change one part of set - transfer to c_1). After $[S_{n-2b+1}]$ has been investigated, however, a large number of new columns must be investigated, so that it is most convenient

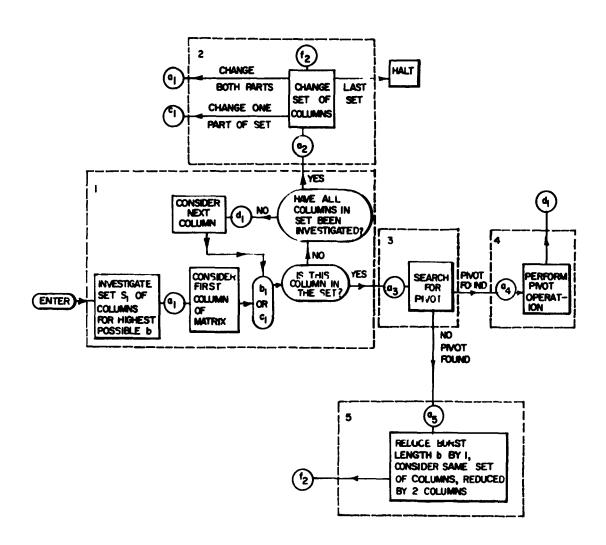

FIG. 6

MAIN EVALUATION PROGRAM - GENERAL DIAGRAM

to investigate all columns of the new set, even though there is a slight duplication of effort. (Change both parts of set - transfer to a,).

If some set $[S_1]$ is found to be linearly dependent, then not all bursts of length b or less can be corrected for the chosen value of b. The value of b is then reduced by one (reduce burst length - part 5), the number of columns per set by two, and the search is continued (transfer to f_2). It is not necessary to begin all over again' when the burst length has been reduced, since all sets found linearly independent include sets for smaller values of b. If, for example, the set j to $b_0 + j - 1$, k to $b_0 + k - 1$ was the last to have been found linearly independent, the search can continue starting with j + 1 to $b_0 + j - 1$, k + 1 to $b_0 + k - 1$. Actually, for convenience, some duplication has been permitted, and the search continues starting with j + 1 to $b_0 + j - 1$, $b_0 + j$ to $2b_0 + j - 2$.

The total number of submatrices to be investigated increases as the square of the code length. This property ensures that the computer does not have to compete with an exponential growth of computations with code length, as would be the case if each error burst had to be individually generated and checked.

Further details of the code evaluation procedure are given in Appendix D.

D-4. Best Codes

A program which permits both construction and evaluation

is capable of finding a "best" code. For example, to find a code capable of correcting all bursts of length b or less, the computer could generate a code, test its capability to correct bursts of length b or less and, if it could not, generate another code. However, the pb 250 program is too slow (about 2-4 hours per code) to make this procedure practical if the fraction of codes correcting all bursts up to length b is very small.

E. Conclusions

Two programs have been described for the construction of codes suitable for the burst-error correction procedure described in reference (1). Also, a program for evaluating the burst-error correcting capabilities of the constructed code has been presented. The general logical procedures described are valid for any code length, n, and number of check digits, c. The specific pb 250 programs were written for n = 100 and c = 50, but with minor modifications they could be used for any $n \le 105$ and $c \le 63$. (These modifications are explained in Appendix G). Larger codes could also be handled if additional memory lines were available.

The first method of construction is preferable given the present programs, because it is more compatible with the evaluation program and requires fewer manual operations.

The evaluation program permits determination of the burst-error correction capabilities (maximum value of b) for any group code, not just the class under consideration.

APPENDIX A

Characteristics of the pb 250 and Conventions Used

The Appendices to follow contain various descriptions of the programs constructed. Some of the discussion is general, but other parts will be intelligible only to someone familiar with the Packard-Bell pb 250 computer, and are presented chiefly for reference value. However, a few basic pb 250 characteristics and conventions used are explained here as an aid to understanding the principal ideas.

The pb 250 stores data or commands in a number of lines, each containing 256 sectors numbered (octally) from 000 through 377 (400 octal = 256 decimal). The lines available on the particular machine used are numbered 00, 01, 02, 03, 04, 05, 06, and 07. Each command location stores 21 bits plus a sign bit. There are also three arithmetic registers, labelled A, B, and C.

The following conventions are employed in the pb 250 logic diagrams to follow:

- (1) Parentheses signify "contents of".
- (2) A long dash, as (A)———(B), implies contents of A replace contents of B.
- (3) Three-figure numbers, as OO2, signify octal sector numbers.
- (4) Two-figure numbers, as O2, signify octal line numbers.
- (5) The number at the upper right corner is the address of the first instruction in the box - sector number followed by line number.

- (6) The words "(A) and (B)" signify the logical product of (A) and (B) as binary sequences. A one is placed in every position of "(A) and (B)", where both (A) and (B) contain a one. A zero is placed in all other positions.
- (7) The words "(A) or (B)" signify the logical sum of (A) and (B).
 A one is placed in every position of "(A) or (B)" where either
 (A) or (B) or both contain a one. A zero is placed in all other positions.
- (8) A connector (a_i) has a subscript i which indicates it is in the ith section of the program.

APPENDIX B

Code Construction Program - First Method

1. Generation of a Random Code

The process of generating a random code consists of selecting n - c columns of the [P] matrix as random sequences of zeroes and ones, and of selecting a unit diagonal matrix for the c columns corresponding to the positions to be occupied by check digits. The key as to which columns are to contain the unit diagonal matrix is contained as a set of numbers in sector 277, lines 02, 03, 04, 05, and 06. The location of zeroes in these numbers corresponds to the c columns of the matrix [P] (located in the first n columns of sectors 300-377, lines 02, 03, 04, 05, and 06), which contain the unit diagonal matrix. For the (100,50) code with check digits in position 26-75, the key numbers are, in octal form,

277 02\$ +7777777 277 03\$ +7400000 277 04\$ +0000000 277 05\$ +0000777 277 06\$ +7777740

The columns corresponding to ones in the 277 sector numbers are filled with random numbers. The manner in which this is done is illustrated in Figures 7-8. Conventions used are as described in Appendix A.

Part 1 of the Random Code Generation Program (figure 7) consist of filling in the random numbers. Initially, some randomly-chosen positive 21-bit number is placed in (R). The first random number

generated in the minor product of (R) with +7303425 (octal) which is the highest power of five capable of being placed in one location. This minor product then replaces (R) for use in generating the second random number. The digit-by-digit logical product of the first random number with the contents of 277 02 are placed in 301 02 to form the first 21 bits in the first row of matrix [P]. Similarly, all the addresses from 301 through 362, line 02, are filled with random numbers. The program then moves to line 03, etc. The initial, or "key" random number R is stored in 240 05.

Part 2 of the Random Code Generation Program (shown in figure 8) is for the purpose of inserting the unit diagonal matrix. Beginning with +4000000 (octal) in (d), the contents of d are shifted and compared with the contents of sector 277 (first line 02, then line 03, etc.) until the single one in (d) corresponds in position to a zero in (277,x). Then the binary digit-by-digit logical sum of (d) with (301,x) is stored in (301,x). The contents of d are shifted once more and the new contents stored in (302,x) (unless, just previously, (d) = +0000001, in which case +4000000 would be stored in (302,x+01)). Each time (d) is stored, the sector address key S is incremented by one, but each time (d) has a one in a position corresponding to a one in (277,x) the key S is not incremented, and (d) is not stored. After line 06 has been passed, the construction is complete.

2. Suitability of the Code

The above discussion has described the details of the

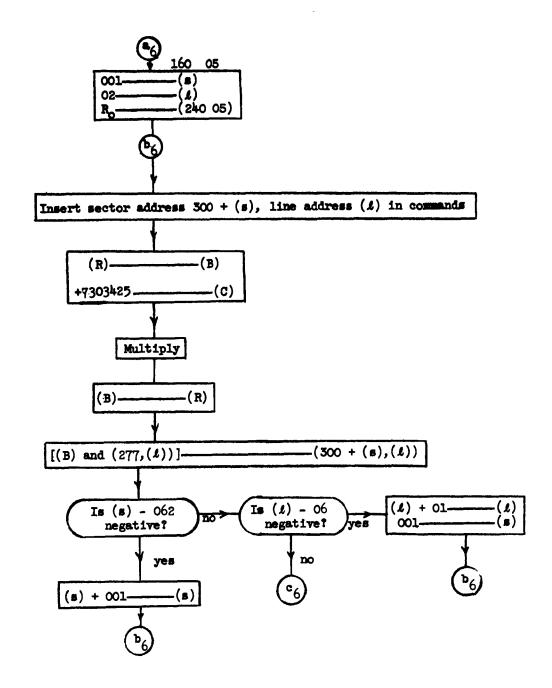

Figure 7 - Random Code Generation - Part 1

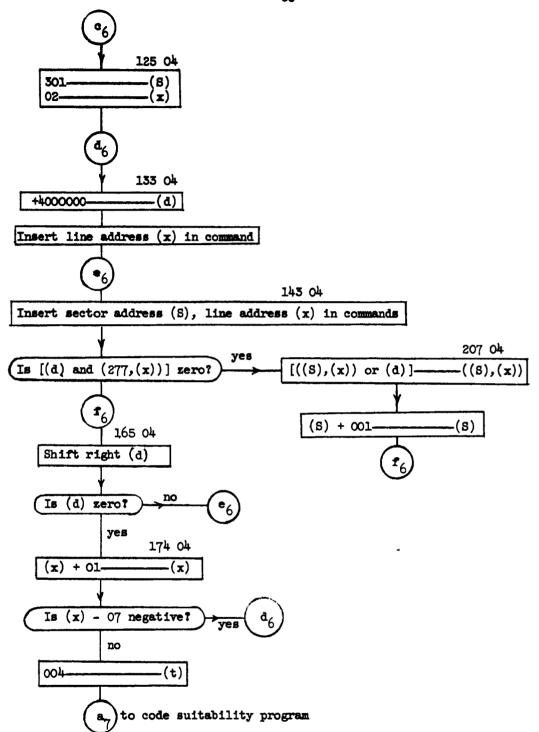

Figure 8 - Random Code Generation - Part 2

"Generate Random Code" box in figure 5, Section C.1. The following is a description of the remaining parts of figure 5.

A key is first set up to indicate for which sets of columns linear independence is to be searched. For the (100,50) code this is set up as follows.

line	→ 02	03	04	05	06
secto	r				
267	-7777777	-7400000	+0000000	+0000000	+00000000
270	+0000000	+0377777	-7760000	+00000000	+00000000
271	+00000000	+0000000	+0017777	-7777000	+00000000
272	+0000000	+0000000	+0000000	+0000777	-7777740

For other codes, sectors 273, 274, 275, and 276, are also available to permit linear independence search over more sets of matrices. In the present case, keys 267 and 270 are used to search for linear independence of columns 1-50, while 271 and 272 are used to search columns 51-100. In the program, the keys to be used are expressed as 267 + (p), 270 + (p).

Figure 9 shows the logic diagram. Initially, p = 0 is set.

Most of the logic shown is for the purpose of adapting the main evaluation program to the present requirements. The number +7000000 is placed in a key position in the main program to cause it to branch differently from its normal procedure. (The dashed lines indicate the paths normally taken by the main program. See Section D and Appendix D for a description of the main program).

The section beginning with Ol4 O4 places the contents of 267 +(p) and 270 +(p), lines O2 through O6, in that part of the main

program which determines the set of columns to be searched for linear independence (quantities X and Y in the main program). In order that the code be suitable it is necessary that columns 1-50 be linearly independent and that columns 51-100 be linearly independent. (Columns 26-75 are already linearly independent by construction). Thus, the search is first run through for p = 0, then for p = 2. If the set for p = 0 is found linearly dependent, a new code is generated.

The time required to generate a code is about 15 seconds. It requires 3 or 5 minutes to determine if the code is suitable. The time required to find a suitable code is variable, usually between 1/2 and 1 hour for a (100,50) code.

The coding matrix obtained in the above manner appears in a mixed form. To obtain a usable form, it is necessary to interchange rows such that the ith row represents the ith check rule of the code. This is done by the procedure illustrated in figure 10.

Again, the main evaluation program is used for the bulk of the operations. A key of +7700000 is placed in (Y₀,02) to obtain proper branching. Then, the main evaluation program is entered. Suppose that columns 51-100 are the ones under consideration. These columns already each contain exactly a single one, but the one is generally not in the desired position. The first column considered is column 51, and (1) is set equal to 001. The search for pivot (see Appendix D) discovers a one in row j of column 51. The key then causes the program to branch to 325 07 instead of proceeding to "perform pivot operation". The portion of the program following 325 07 interchanges

row i and row j of the matrix. Column 51 now contains a one only in row one. The number (i) is then increased by OOl, and the main program re-entered at d_1 , where the column under consideration is shifted to 52.

After fifty interchanges have been made, (1) - 063 (octal) will be zero, and the program will halt. A unit diagonal matrix now appears in columns 51-100. To observe the decoding matrix with columns 1-50 diagonalized, the program is entered at , where (p) and (x) are both set equal to 000 (see figure 9). The code suitability program is then run through for just (p) = 000, yielding single ones in each of columns 1-50. The rows are then interchanged by the "Interchange to diagonal" program. Similarly, to observe the 26-75 diagonalized decoding matrix, (a₁₀) is the entry, and (p) = 001 is used. Entry at (a₁₁) will return to the 51-100 diagonalized matrix.

Once a suitable code has been found, it can be regenerated at any time by inserting the key number for that code in 201 05 and performing the random code generation program.

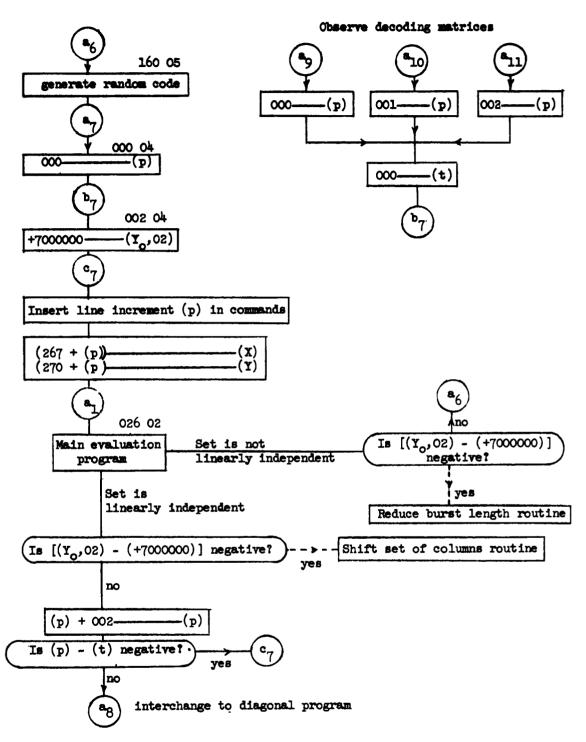

Figure 9 - Determination of Code Suitability and Observation of Decoding Matrices

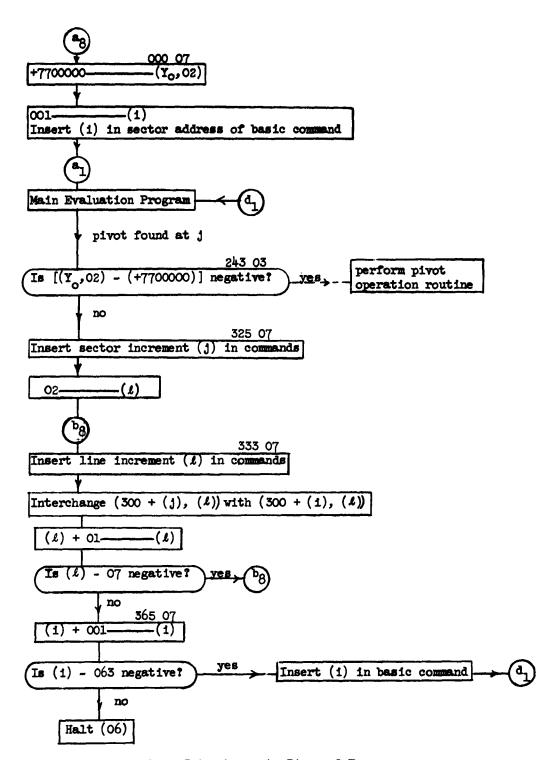

Figure 10 - Interchange to Diagonal Program

APPENDIX C

Code Construction Program - Second Method

1. Theory

The matrix $[M_i]$ may be considered as defined by the product of matrices

$$[M_1] = [T_{05}][T_{04}] \dots [T_1]$$

where

and the $d_{i,j}$, for all j except j = i, are chosen at random. The matrix $[T_i]$ represents the operation of replacing the i^{th} row by the modulo two sum of the i^{th} row with a random selection of the other rows. It can readily be shown by taking the product that

$$[T_{\underline{i}}][T_{\underline{i}}] = [I]$$
 (18)

From (18), it follows that the inverse of M_1 is given by

$$[M_1]^{-1} = [T_1][T_2] \dots [T_{95}],$$
 (19)

since

$$\{[T_1][T_2] \dots [T_{25}]\}\{[T_{25}] \dots [T_2][T_1]\} = [I]$$
 (20)

Thus, if a matrix is formed by using a set of row combination rules as above, its inverse is found by performing the combinations in reverse order. This allows the use of practically the same computer program to obtain both a matrix and its inverse.

The product of two matrices can also be found with only a slight change in the basic program. The ith row of the product [A][B] is the modulo two digit-by-digit sum of those rows of [B] such that the jth row is included in the sum if and only if digit a_{ij} of [A] is a one. This operation is very similar to that performed in constructing [M_i]. If [A] replaces the row combination rules, [B] replaces the diagonal matrix, and if the sum of rows is stored in a new location instead of replacing the old row of [B], the program used for constructing [M_i] can be used to find the product [A][B].

2. Description of the pb 250 Program

Although only 25 x 25 matrices are being constructed, the program permits construction, inversion, and products of matrices of any size up to 63 x 63 without modification. The key which tells the program when to stop is a negative number placed after the last combination rule. The combination rules were stored in sectors 201 through 231, lines 02 and 03, the first 21 digits of a row being stored in line 02, and the remaining 4 in line 03 (with a + sign). If a larger matrix were used, sectors 201-276 are available, and each combination could be stored in lines 02, 03, and 04, making up to 63 (decimal) dimensions possible.

Figure 11 shows the basic outline of the matrix construction program. Random numbers are generated to form the combination rules. To find a matrix and its inverse, a unit diagonal matrix is initially stored in sectors 301 through 377, lines 02, 03, and 04. The resultant matrix or inverse will appear in these locations upon completion of the program. The program is divided for convenience into five separate parts, which are individually described in figures 12-17. Conventions are as described in Appendix A.

Part 1 (Figure 12)

This section describes the main program. The three boxes indicated by asterisks are modified according to whether the purpose is to construct a matrix, find its inverse, or find the product of two matrices. An index (i) specifies the sector address of the combination rule (or row of matrix A in the product AB), while (j) corresponds to the jth digit of the combination rule. If the jth digit is a one, row j of the matrix stored in 301-377, lines 02-04, is added digit-by-digit modulo two to the basic row i of that matrix, or of the product matrix in the case where the product is taken.

The program initially picks up line 02 of the combination rule corresponding to (i_0) . This is tested to see if it is negative, since a negative number indicates that all combination rules have already been considered. If it is positive, the rule is stored in (T), and the number 25 (octal) = 21 (decimal) is stored in (s) to specify the number of digits of this part of the combination rule which are yet to be considered. The number (T) is then placed in register (B) and shifted left,

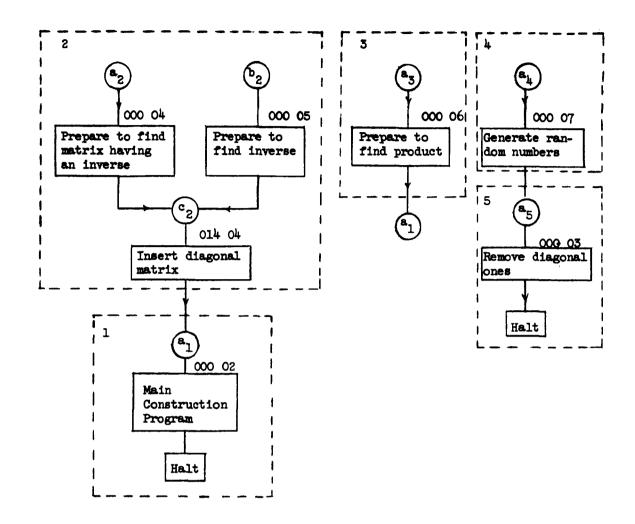

Figure 11 - Second Method of Code Construction

while simultaneously (s), which has been placed in register (C), is decremented by one. The number (C) is then tested for sign. If it were negative, this would indicate that all 21 digits of the combination rule had been considered. In this case, however, the number is positive. Then, (B) is tested for sign. If the first digit of the combination rule were a one, this digit would be shifted into the sign position of (B), yielding a negative number. If the first digit were a zero, the shift would yield a positive (B). Thus, if (B) is negative, row j is added to row i to form a new row i. (This never happens for i = j because the combination rules are generated such that the ith digit of rule i is always a zero.) Then, the program proceeds to g₁ and j is incremented by one. If (B) is positive, the program proceeds directly to g₁. The number (j) continues to be incremented once per loop and (s) decremented until (s) is negative.

Then, the line address increment (q) of the combination rule is incremented by one. If the resulting (q) -03 is then non-negative, the entire combination rule has been considered, in which case a new rule is selected. This is done by incrementing (i) by 001 for matrix construction or product formation, or by decrementing (i) by 001 if the inverse is being sought.

In performing the addition of rows i and j, basic sector numbers (S_O) and (L_O) are inserted. For matrix construction or inversion, (S_O) = 300 and (L_O) = 02, while for product formation (S_O) = 200 and (L_O) = 05.

Part 2 (Figures 13-14)

To construct a matrix given the combination rules, the program is started at 000 04. The section from a_9 to c_9 modifies the main program for the reasons explained in Part 1. The program following c_9 inserts a diagonal matrix in sectors 301-377, lines 02-04. The section between c_9 and c_9 clears to zero the contents of sectors 301-377, lines 02-04. Ones are then inserted along the diagonal in the section following c_9 . First, the number c_9 and c_9 the number c_9 is stored in (301 02). The number c_9 is then successively shifted right one unit at a time, each time storing the new number in the next successive sector number location of line 02, until c_9 is shifted to zero, in which case c_9 in the case c_9 in the case c_9 in the case c_9 in the program then proceeds to c_9 .

To find the inverse, the program is started at 000 05. The section from (b_p) to (c_p) modifies the main program for reasons explained in Part 1. The remainder of the program is then the same as for constructing a matrix.

Part 3 (Figure 15)

To find the product AB of matrices A and B, the program is started at 000 06. Previously, matrix A is stored in sectors 201-277, lines 02-04, and B is stored in sectors 301-377, lines 02-04. The product appears in sectors 200-277, lines 05-07. The section from b₀ to clears to zero the contents of sectors 200-277, lines 05-07. The main program is then entered.

Part 4 (Figure 16)

This section generates the random combination rules needed to construct a matrix. This procedure is much the same as the one described in Appendix B (Figure 7 and associated explanation). A key number in sector 177, lines 02, 03, and 04, tells the program where random numbers should be placed. For a 25 x 25 matrix, the key is:

177 02\$ +7777777 177 03\$ +7400000 177 04\$ +0000000

The columns corresponding to ones in the 177 sector numbers are filled with random numbers. The other columns are filled with zeros. After the random numbers are generated, the program proceeds to $\begin{pmatrix} a_5 \end{pmatrix}$.

Part 5 (Figure 17)

It is necessary to remove the diagonal ones from the set of random numbers in order to ensure that the ith digit of combination rule i is always a zero. Initially, (W) = -37777777 is set, and the contents of 201 02 are replaced by the digit-by-digit logical product of (W) with the previous contents of 201 02. The number (W) is then successively shifted right one unit at a time (the nimus sign causes ones to be introduced from the left), each time taking the logical product of (W) with the contents of the next successive sector number location of line 02, until (W) becomes equal to -77777777, in which case the line address is incremented to 03, and (W) is returned to -37777777. This continues until all sectors through 277 have been included. The program then halts.

APPENDIX D

Details of the Code Evaluation Program

Figures 18-22 show the logic of the various parts of the evaluation program in greater detail. The five parts are the same as referred to in figure 7. The notation used is similar to that described in Appendix A with an additional special convention. Since some quantities, as Y and X, represent contents stored in more than one location (the same sector, but different lines, the notation (Y, O2) will represent the contents of line O2 of the sector address of Y, while the notation (Y) will represent the contents of all lines in which Y is stored.

The 50 x 100 matrix [P] is stored in sectors 301-362, lines 02 through 06. The addresses in lines 02, 03, 04, and 05 each contain 21 bits of a row of the matrix, while only 16 bits from the addresses in line 06 are included. (Since $4 \times 21 + 16 = 100$).

The operation of the program is best understood by considering the various parts and their purposes.

Part 1 (Figure (18)

The purpose of Part 1 is to select the column for which a pivot search is to be carried out. Before this can be done, the set of columns currently being searched for linear independence must be specified. This set is defined by the quantities X and Y. The quantity X is a 100-digit number stored in lines 02, 03, 04, 05, and part of 06, sector 260, and consists of zeros except for a sequence of b successive ones. The

quantity Y is another 100-digit number, stored in lines O2, O3, O4, O5, and O6, sector 261, and also has ones only in b successive positions, but none in position corresponding to ones in X. A given pair X, Y define some set $[8_1]$ of columns of the type described in Section D-3. The part of the program beginning at OOO O2 sets X, Y, and Y₀ (which will be discussed later) to the initial values corresponding to $[8_1]$ and the value of b.

A number is required to keep a record of the column under consideration. This is provided by (P), together with line address (x). The binary number (P) contains but a single one, that being in the position corresponding to the column under consideration, and (x) gives the line address of the column under consideration. A convenient related quantity is (P_g) , which is a 100-digit number stored in lines O(2), O(3), O(4), O(5), and O(6) of sector O(6). This number is to contain a one in all those positions up to, and including, the column under consideration.

Following a_1 , (P) and (P_S) are set to their initial values, which corresponds to consideration of the first column. To determine if the column under consideration is in the set, it is necessary only to compare (P) with line x of X and of Y. If it is, a search for pivot is made on that column (proceed to a_0). If not, there are two possibilities: either the set to be investigated has not yet been reached, or it has been passed (in which case all columns have been investigated. These alternatives are separated by determining whether (P_S) has any ones in common with Y. If it does, all columns have been investigated, and a new set of columns is selected (to a_0). If not, (P) is shifted

right one space to consider a new column. If the right shift causes (P) to be zero, the new column should be the first in the succeeding line address, so that x is incremented by 01 and (P) is reset to +4000000. Also, line x of P_g is set to -4000000. The negative sign is used for P_g because the minus sign is represented in the computer as a one, and this one is shifted right on a right shift command, while retaining the minus sign. Thus, successive right shifts change -4000000 to -6000000 to -7000000, etc. When (P) is not zero after shifting, line x of (P_g) is shifted right one space. In the latter case, the program then returns to c_1 . In the former, however, where x has been changed, the return must be to c_1 in order to change x in certain commands.

Part 2 (Figure 19)

This section provides a change in the set of columns for which linear independence is being searched. The order of searching is as follows: begin with X covering columns 1 to b, and $Y = Y_O$ covering columns b + 1 to 2b. Then shift Y one space right until the last column covered by Y is the one-hundredth. The next step is to shift X and Y_O one space right and set $Y = Y_O$. The number Y is then shifted, and shifting-continues in this manner until Y_O covers the one-hundredth column position.

The test following (a_8) is to determine whether Y has reached position 100. If not, a key V is set for shifting Y. If it is, the key is set for shifting Y_O. Shifts of X, Y, and Y_O all share the same subroutine.

The process of shifting X, Y, or Yo is somewhat complex because each occupies five separate addresses. However, advantage can be taken of the fact that the non-zero elements appear in succession. First, a search is made for the lowest line-numbered address & of V for which the contents of V, (1) are non-zero. This number in V, (1) is placed in register A. If (A) is now negative, the sign must be made positive, in order that the subsequent right shift of (A) will introduce a zero from the left. The contents of registers A and B are then shifted right one position. The new value of (A) is then stored in (V, (1)). If the last digit in the original V, (1) were a zero, the shift will cause (B) to become positive. In this case, the shifting of V is complete. If the shift causes (B) to become negative, there are two possibilities: if (V, (L) + 0L) were zero, it should now be made +4000000, and shifting is then complete; if (V, (L) + Ol) is non-zero, the remainder of the shift can be accomplished after observing the highest line-numbered address q of V for which the contents of V, (q) are non-zero. When such a non-zero V, (q) is found and stored in (A), it is shifted right one place, and the new (A) replaces (V, (q)). If (B) is now negative, -4000000 is placed in (V, (q) + 01). The shift of V is then complete.

 If not, the program returns to e_1 and begins considering columns, starting with the first. If the key is Y, only one new column is introduced in the new set, so that the return is to e_1 to consider just that new column.

Part 3 (Figure 20)

The purpose of this section is to search for a pivot element in a particular column; i.e., a non-zero element preceded in its row by all seros in the columns of the set under investigation. The first step is to set up a quantity Z, stored in lines 02, 03, 04, 05, and 06 of sector 121, which contains ones just in those positions of columns of the set under investigation which have been considered, including the present one. A one is placed in a position of Z if and only if it appears as a one both in P_a and in either X or Y.

Using the quantities (P) and (x) which specify the column, the rows are next searched to find one with a one in that column. If one is found for some sector address (300 + j), a comparison is made to see if there are any non-zero elements in row j corresponding to non-zero elements of Z, exclusive of the particular pivot column. If there are none, this row is a suitable pivot, and the program proceeds to (perform pivot operation). If it is not a suitable pivot, j is incremented by one, and the search is repeated for a new row. If all rows of the matrix have been searched without success, it is known that the set of columns is linearly dependent. The program then proceeds to (reduce burst length).

Part 4 (Figure 21)

The purpose of this section is to perform the pivot operation; i.e., to add the pivot row (row j) digit-by-digit modulo two to all other rows which contain a non-zero element in the column under consideration. The parameter (k) specifies the row to which possible addition of row j is being considered. The case k = j is eliminated from consideration at 003 06. Otherwise, if a non-zero element is found in the proper column, row j is added to row k, the sum forming a new row k. The addition must be carried out for line addresses s = 02, 03, 04, 05, and 06. Computer speed is most critical in the section from 017 07 ($\binom{c_4}{c_4}$) through 143 06. Each command in this section must be excuted about 250,000 times in the course of the program. For this reason all but 3 of the 24 commands in this section are sequence tagged for rapid operation.

Part 5 (Figure 22)

This section causes the maximum burst length b to be reduced by one unit if a linearly dependent set of columns has been found using the previous value of b.

Suppose that the set found to be linearly dependent consists of columns x to b + x - 1 and y to b + y - 1 (we must have $y \ge b + x$). All column sets previous to this set were found linearly independent for the value b. It is then only necessary to begin the search with b - 1 at the set of columns x + 1 to b + x - 1 and y + 1 to b + y - 1, because all previous sets of columns for burst length b - 1 have been included in the search with burst length b. For convenience, however, some duplication is permitted, and the new search starts with x + 1 to b + x - 1

and b + x to 2b + x - 2. The program shown removes a single one from the right of the sequence of ones in X and Y_O. (Previous to the change, the sequence of ones in Y_O was from b + x to 2b + x - 1.) It is actually desired to have a one removed from the extreme left of X rather than the right, and this is corrected when the program proceeds to f_{2} and shifts X (but not Y_O) right one place. Then (Y_O) ——— (Y), and the program proceeds to f_{2} .

The ones are removed in the following manner. First the sector address key 264 is set, which is the address of Y_0 . Then, a number K containing a single one, initially +0000001 in line 06, is shifted left and compared with the contents of 264 having the same line address until the two compared numbers have a one in common. If K is shifted left until it becomes -0000000, the line address is reduced by 01, and K is again replaced by +0000001. When a common one is formed, K is subtracted from the contents of 264, line I, and the key 260 is set, which is the address of X. After the process is repeated for 260, the program proceeds to (f_2) for shifting X right and (Y) —— (Y).

APPENDIX E

List of Programs

1. Evaluation Program and First Construction Method

The programs described in Appendices B and D can all be stored in the computer at the same time. The commands are listed in figure 23 as read out from the computer. All locations containing a number with a line through it need not be read into the computer. Some of these locations are not used, while others are filled in the course of the program.

The contents of sectors 301-362, lines 02-06, which are not shown, contain the coding matrix.

2. Second Construction Method

Figure 24 lists the commands for this program. These commands cannot be stored in the computer at the same time as the evaluation program.

Figure 24e - List of Second Construction Method Commands-Line 07 and Sector 177

APPENDIX F

Adaptability to Other Code Sizes

The following is an enumeration of the changes which must be made according to the value of n and c chosen.

1. Number of Rows of Matrix

372 07\$ 0XX 0000; 206 06\$ 0XX 0000; 231 03\$ 0XX 0000; 214 05\$ 0YY 0000; XX = 1 + (C)octal; YY = (C)octal

The above quantities specify when the last row has been reached.

2. Number of Columns of Matrix

for n = 100, 217 02\$ 267 040X; 217 02\$ 261 0406; 221 02\$ +XXXXXXXX 221 02\$ +0000077

This command and number tell the program if the set of columns Y has reached inclusion of column n. If one writes n=2lp+q+1, where q<2l, then the line address of the command in 217 02 should be 02 + p, and the number in 221 02 should contain zeros in the leftmost q positions, and ones in the remaining positions.

Also

This command and number tell the program if the set of columns Y_0 has reached inclusion of column n. (Logically, it would appear from the program that n + 1 should be used instead of n, but the search for linear independence over the last set of columns is redundant because of the method of code construction.)

3. Key for Generating Code

The first n digits of those beginning with the leftmost in 277 O2 and ending with the rightmost in 277 O6 correspond in position to the n columns of the [P] matrix. A set of c consecutive digits of these are made zero, and the other n - c are each set equal to one. The c zeros correspond to the positions of the check digits. The code generation program fills the columns corresponding to ones in 277 with random numbers, and places a c x c unit diagonal matrix in the check digit positions. In certain cases it will be necessary to use a sector address other then 277, as explained below.

4. Key for Decoding Matrices

267-276, lines 02, 03, 04, 05, 06

In order for a code to be suitable, certain sets of columns of [P] must be linearly independent, namely $[P_1]$, $[P_g]$, ..., $[P_q]$. Sectors 267, 270 are filled such that each position corresponding to a column of $[P_1]$ contains a one in either 267 or 270, and all other positions are zero in both 267 and 270. The contents of 267 and 270 replace the quantities X and Y in the main program to provide a test of the linear independence of $[P_1]$. For the (100, 50) code, the following were the contents:

Similarly, 271 and 272 can represent $[P_2]$, etc. (In some cases, 270 and 271 together can represent one of the matrices as well.)

An additional charge needed is

254 02\$ 0XX 0000;

where $XX = (2q)_{Octal}$, and q is the number of matrices which must be linearly independent in order to make the code suitable. In case q > 4, it is necessary for the decoding matrix key to occupy sectors 277 and some succeeding sectors. This will only happen if c is considerably below the maximum, in which case the first row of the [P] matrix can be stored further down than sector 301. The key for generating the code would also

have to be moved to a sector other than 277. This would require the following changes.

Replace 300 4200; by XXX 4200; in

047 02

103 02

061 04

Replace 300 0500; by XXX 0500; in

112 04

007 05

251 07

Replace 300 1200; by XXX 1200; in

042 05

170 05 .

Replace 300 0400; by XXX 0400; in

256 07 .

Replace 300 0000; by YYY 0000; in

126 04 .

Replace 277 4200; by ZZZ 4200; in

137 04 .

The quantity YYY is the sector location of the first row, and XXX = YYY - OOl. The address ZZZ is for the new key location.

APPENDIX G

Checking the Computer Result

In the course of the main evaluation program, the computer executes more than ten million commands. While it is very unlikely that a computer error would occur without being coupled with a premature halt in the program, it was felt that some check was needed to ensure that the computer performed the program correctly.

An error committed in performing the various additions of rows to the matrix could readily be detected by operating on the final derived matrix after computer halt so as to re-diagonalize columns 51 - 100. This is done simply by starting the program at 017 05 (a1) in Figure 9, Appendix B). If the resulting matrix is not identical to [P], then some error has been made, while if it is identical, then it is virtually certain that no error has been made in performing the additions of rows to other rows. No such error was ever observed.

An additional check on errors is to run the program through twice and compare the two final derived matrices. This was done for the code described in Section B, and the same result was obtained in both cases.

The code shown in Appendix H was checked in a different manner, in addition to the check by return to [P]. Instead of the "reduced burst length" portion of the program, the computer was caused to halt when search at that burst length yielded a set of linearly dependent

columns. The program halted for bursts of length 21, and visual observation showed that the set of columns (3-23, 53-73) were indeed linearly dependent (see figure 25, especially column 73). As a further check, a return to the original matrix was made, and this same set of columns was checked for linear independence. Again, the set was found linearly dependent. The same was done for b = 20, and b = 19. Finally, the program ran to completion for b = 18. This final result was checked further by return to the original matrix [P].

Figure 25 - Transformed Code of Appendix H Showing Linear Dependence of Columns 3-23, 53-73

APPENDIX H

An Additional (100, 50) Code

Figures 26-28 illustrate the coding and decoding matrices for a (100, 50) code which is capable of correcting all bursts of length 18 or less. This code was constructed by means of the second method of code construction, as described in Section C.2 and Appendix C. The individual 25 x 25 matrices from which the code was built are shown in figure 29, and related matrices are shown in figure 30. Octal digits represent three binary digits in a row, except the last octal digit, which is either 4 or 0 according as the last binary digit is 1 or 0.

APCHL-63-28	COMPUTER CONSTRUCTION AND EVALUATION OF LONG BURST-ERROR CORNECTING	Twalth Scientific Physic, 31 January 1963, 59 + vii pp. including 30 figures, 6 references, distribution list. UNCLASSITID REPORT	This report presents a specific method of programming a digital computer to construct and evaluate occus mattable for uses in a busticeror occurection decoding scheme described in the Twith Scientific Report. Two (100,50) codes of this type have been constructed using the method absorbbed. One is found oupship of correcting uniquely all bursts of length 22 or less.	The method used to evaluate burst-error correcting capabilities is applicable to any group oces, not just the class under consideration. Hencey listitations have restricted the present program to code language not exceeding 107 digits, of which at most 63 may be check digits.	AD Accession No.	Electronics Research Directorate, Air Force Cambridge Research Laboratories, Office of Aeropace Research, United States Air Force, Bedford, Nessechments.	APCHL63-28	CONCURS COMPRESSION AND EVALUATION OF LONG BUNET-ENDOR COMPANIES.	Tealth Scientific Report, 31 January 1963, 89 + vis pp. including 30 figure, 6 references, distribution list. UNCLASSIFIED MROOT	This report presents a specific method of programming a digital computer to constitute and wealuate codes saitable for use in a bargi- error correction decoding echams described in the Testh Scientific Suport. Pro (100, 50) codes of this type have been constructed using the marbod described. One is found capable of correcting uniquely all bursts of length 21 or less	The method used to evaluate burst-error correcting capabilities is applicable to any group ords, not just the class under consideration, beaugy lastitudes have restricted the present program to code languas not exceeding 107 digits, of which at most 63 may be check digits.

APCHL-63-28	COMPUTER COMPTROCTION AND EVALUATION OF LONG BURST-ERROR CORRECTING SYSTEM	Posita Beleatific Report, 3 January 1963, 89 + vil pp. including 39 figures, 6 references; distribution list. URCASSIFIED REPORT	This report presents a specific sethod of programming a digital computer to contract and walket codes entiable for use in a burst- error correction decoding scheme described in the Tank Scientific fibrort. Two (100,50) codes of this type have been constructed using the methods electribed. One is found capable of correcting uniquely all bursts of langth 21 or less.	The method used to evaluate burst-error correcting capabilities is applicable to any group code, not just the class under consideration. Hencey limitations have restricted the present program to code incuba not exceeding 105 digits, of which at most 63 may be check digits.	AD Accession Bo.	Electronics Research Directorate, Air Force Cambridge Research Laborators, Crite of Aerospece Research, United States Air Force, Badford, Messenbustts.	APCHL-63-28	COMPUTER COMPTRUCTION AND EVALUATION OF LONG BURST-ERROR CORRECTING COMPS.	Twairth Scientific Report, 31 January 1963, 89 + vil pp. including 30 figures, 6 references; distribution list. UNCLASSIFED REPORT	This report presents a specific method of programming a digital computer to contract and welcute codes satisable for use in a brist-serve correction decoding scheme described in the Trait Scientific Maport. The (LOLO)S) codes of this type have been constructed using the methods described. One is found capable of correcting uniquely all bursts of length 21 or less.	The method used to evaluate burst-error correcting capabilities is applicable to any group code, not just the class under consideration. Hemory lastistican have restricted the present program to code lengths not exceeding 10% digits, of which at most 63 may be check digits.

The Research Division of the College of Engineering is an integral part of the educational program of the College. The faculty of the College takes part in the work of the Research Division, often serving as co-ordinators or project directors or as technical specialists on the projects. This research activity enriches the educational experience of their students since it enables the faculty to be practicing scientists and engineers, in close touch with developments and current problems in their field of specialization. At the same time, this arrangement makes available to industrial and governmental sponsors the wealth of experience and special training represented by the faculty of a major engineering college. The staff of the Division is drawn from many areas of engineering and research. It includes men formerly with the research divisions of industry, governmental and public agencies, and independent research organizations.

Following are the areas represented in the research program: Aeronautical Engineering, Chemical Engineering, Civil Engineering, Electrical Engineering, Engineering Mechanics, Industrial and Management Engineering, Mechanical Engineering, Metallurgical Engineering, Mathermatics, Meteorology and Oceanography, and Physics. In addition, an interdisciplinary research group is responsible for studies which embrace several disciplines. Inquiries regarding specific areas of research may be addressed to the Director, Research Division for forwarding to the appropriate research group.
